**Introduction:** Presolar SiC grains have been divided into subtypes based on their C and Si isotopic compositions [1]. The search for rare types of grains has been facilitated by the development of an automatic grain mode analysis program for the NanoSIMS [2]. We report results from the automatic analysis of SiC grains of sizes 0.5–0.8  $\mu\text{m}$  from the KJE size separate of the Murchison meteorite [3].

**Experimental:** For the automatic grain analysis the C and Si isotopes were measured in multidetection by rastering a primary  $\text{Cs}^+$  beam over 40 x 40  $\mu\text{m}^2$  large areas. After identification of different grain types, N and S isotopic measurements were made on selected grains in imaging mode in order to assess possible S contamination. This was followed by Al-Mg and Ca-Ti isotopic analyses to look for the initial presence of  $^{26}\text{Al}$  and  $^{44}\text{Ti}$ .

**Results and Discussion:** Among 1118 analyzed grains we found 63 SiC AB grains (5.7%), one C grain (0.1%), 17 X grains (1.5%), 64 Y grains (5.8%), 55 Z grains (5.0%), 5 nova candidates (0.5%) and 5 X-type  $\text{Si}_3\text{N}_4$  grains (0.5%). These abundances are similar to those previously found in somewhat smaller grains [4]. The C grain has  $^{12}\text{C}/^{13}\text{C} = 192$ ,  $^{14}\text{N}/^{15}\text{N} = 58$ ,  $\delta^{29}\text{Si} = 1345 \pm 19\text{‰}$ ,  $\delta^{30}\text{Si} = 1272 \pm 19\text{‰}$ . It has an enormous  $^{32}\text{S}$  excess ( $\delta^{33}\text{S} = -944 \pm 33\text{‰}$ ,  $\delta^{34}\text{S} = -941 \pm 14\text{‰}$ ; see figure). This is the largest  $^{32}\text{S}$  excess ever observed. The S isotopic composition is almost that calculated for the Si/S zone in a  $15M_{\odot}$  SNI model [5]. The C grains has  $\delta^{26}\text{Mg} = 2625 \pm 394\text{‰}$  and  $\delta^{44}\text{Ca} = 974 \pm 213\text{‰}$ , with initial  $^{26}\text{Al}/^{27}\text{Al}$  and  $^{44}\text{Ti}/^{48}\text{Ti}$  ratios of  $1.7 \times 10^{-3}$  and  $4.2 \times 10^{-2}$ , respectively; the first somewhat smaller, the second comparable to values previously found in two C grains [6].

Type X grains tend to have  $^{32}\text{S}$  excesses but errors are large. Still, two grains have  $^{33,34}\text{S}$  deficits of more than  $2\sigma$  and another five grains  $^{34}\text{S}$  deficits of more than  $2\sigma$ . One grain has a  $^{34}\text{S}$  excess of more than  $2\sigma$ . One  $\text{Si}_3\text{N}_4$  grain has extreme C and N ratios ( $^{12}\text{C}/^{13}\text{C} = 7.9$ ,  $^{14}\text{N}/^{15}\text{N} = 4.5$ ), usually indicating a nova origin. However, its Si isotopic ratios are that of an X grain ( $\delta^{29}\text{Si} = -434 \pm 6\text{‰}$ ,  $\delta^{30}\text{Si} = -317 \pm 6\text{‰}$ ), thus a SN origin is more likely. It has marginal  $^{33,34}\text{S}$  deficits, which however, within the errors, are consistent with normal S.
